Abstract—Wireless sensor networks are being considered for use in industrial process and control environments. Unlike traditional deployment scenarios for sensor networks, in which energy preservation is the main design principle, industrial environments stress worker safety and uninterrupted production. To fulfill these requirements, sensor networks must be able to provide performance guarantees for radio communication.

In this article, we consider as a case study the deployment of a sensornet in an oil refinery in Portugal, where sensor nodes are deployed outdoors and might experience high temperature fluctuations. We investigate how the variations of ambient temperature influence data delivery performance and link quality in low-power radio communications. We also study the impact that specific implementation requirements, such as the ATEX fire-safety regulations, can have on the design of the overall network.

Our experiments show that temperature directly affects the communication between sensor nodes, and that significantly less transmission power is required at low temperatures. We further illustrate that it is possible to save up to 16% energy during nights and cold periods of the year, while still ensuring reliable communication among sensor nodes. In view of these experimental results, we elaborate on how the temperature influences both the design and the deployment of wireless sensor networks in industrial environments.

I. INTRODUCTION

Wireless sensor networks are successfully used for applications such as precision agriculture, military surveillance, and environmental monitoring. Recently, sensornets have been considered for use in industrial control and process automation applications because of the benefits obtained from wireless deployment: reduced costs and increased system flexibility.

To support this application domain, sensor networks must assure a certain data transport delay bound and a certain degree of reliability. Unfortunately, most sensor network protocols are designed to preserve energy rather than to meet performance guarantees. Hence, it is necessary to develop new protocols and mechanisms for sensornets that are able to give performance assurances while remaining reasonably efficient.

A sensor network used for process automation and control must be able to deal with fluctuating channels and environmental characteristics. For example, a communication protocol should be able to maintain a requested packet delivery rate also when link reliability drops for a while. When sensor nodes are deployed outdoors, the fluctuations might be high because of changes in weather conditions or in the environment. To be able to design and build protocols that can compensate and deal with varying conditions, the dynamics of channel fluctuations must be characterized.

In this article, we investigate how ambient temperature and weather conditions affect link quality and data delivery in low-power wireless communication. We focus our study on a sensor network deployment in an oil refinery in Portugal. In this context nodes have to be deployed outdoors and must be encased in ATEX-compliant boxes [1] to meet EU fire safety regulations. We investigate the impact that temperature variations and ATEX casing have on the design of sensor networks. Furthermore, we characterize how the energy consumption of sensor nodes is affected by temperature.

Our contributions are threefold. First, we provide experimental results that show how temperature fluctuations can create a significant variation of signal strength of up to 10 dBm. We describe how this may affect the design of applications and communication protocols that must operate outdoors. Second, we show the impact that the introduction of the ATEX casing has on low-power communication. Third, we show that temperature indirectly affects the overall energy consumption of sensor nodes. We also show that it is possible to decrease the transmission power when operating at low temperatures. Thus, nodes can save up to 16% of the power spent for transmitting packets and consequently system lifetime can be improved. In order to evaluate precisely the amount of energy saved, we measured the current consumption of all 32 available output power settings of the widely used CC2420 radio chip. We show that the measured current consumption differs from values commonly used in existing literature.

This article proceeds as follows: Section II provides a description of the application context of our case study. We quantify the impact of temperature on link quality in Section III. Thereafter, we analyze the impact of ATEX-compliant casing on temperature and link quality in Section IV. In Section V we show how the temperature influences the transmission power needed to maintain network connectivity. In Section VI we discuss how the dependency between temperature and link quality affects the network design in our investigated application scenario. After an overview of the related work in Section VII, we conclude the article in Section VIII.

II. APPLICATION CONTEXT

Process automation and control applications have stringent requirements on data transport delay and reliability. In order to understand how such systems operate and the requirements they must meet, we carried out a case study in the context of the GINSENG [2] project. We investigate a wireless sensor...
network deployed for process control and automation in the petrochemical industry.

The GALP [3] oil refinery at Sines, Portugal (see Figure 1) is a complex industrial facility that includes a wide range of processes that must be carefully monitored and controlled. Health and safety are of utmost importance in this environment: fire prevention, safe operation of machinery, and careful handling of products have to be considered when designing a sensornet for such an environment.

A. The Refinery Monitoring and Control System

There are currently 35,000 sensors and actuators in use in the refinery to perform real-time monitoring of industrial operations such as leakage detection, measurement of pressure in the pipes, and control of fluid levels. The extensive monitoring of the refinery provides essential information to ensure a good health of its production processes. In the oil refinery there are 3 systems for monitoring and control the plant: the indicatory system, the control system, and the emergency system. The indicatory system is used to provide the control center with information about status and faults of the equipment, as well as general aspects of the environment. Within this system, information flows one way from the in-field sensors to the control center. Here, the sensor data is typically not vital, but should reach the control center to inform the operators of potential dangers.

The control system is used to control different aspects of the refinery. Information flows in both directions: from in-field sensors to the control center, and from the control center to actuators. In this system it is important that data arrives at its intended destination quickly and reliably. Operators require instant feedback from the sensors because the actuators are used to control equipment.

The emergency system is used to monitor and control mission critical systems, and to trigger alarms in order to prevent an accident. Sensors and actuators in this system are part of a closed loop system without user intervention. The information flowing in these systems is vital, and thus requires the highest level of reliability and the lowest delay bounds.

B. Challenges of a Wireless Monitoring and Control System

Most sensors and actuators in the oil refinery use wired technologies such as 4-20 mA systems. In such industrial environments, the work required to deploy new sensors can be very expensive. Because of their flexibility, wireless sensor networks can be employed to ease and reduce the cost of deployment. At the same time, they must assure the same performance as their wired counterparts do.

When deploying sensors in any industrial setting it is important to consider the environment in which they will be deployed. In the context of the refinery, the sensors will be deployed mostly outdoors and they must meet a number of industrial regulations. Because nodes are deployed outdoors they are exposed to changing weather conditions and, consequently, changing link quality. Temperature changes may affect the link quality as well, so it is important to quantify these effects before designing a sensor network.

The oil refinery deployment further restricts the network design because of its potentially explosive atmosphere. The European Union regulates the equipment used in such contexts as specified in the ATEX directives [1], ensuring that the equipment is not a potential source of ignition. Although it is possible to obtain ATEX certification for a sensor node, the procedure is expensive and time consuming, and needs to be repeated after any modification of the node.

An alternative is to obtain the ATEX certification for a case that will contain the node, as shown in Figure 2. Such enclosures are available from many vendors and can be purchased for about 10 Euros. This is the industry’s preferred way of obtaining ATEX compliance because it is cheaper and more flexible. Obviously there is a risk that the ATEX enclosure affects the communication links since the sensor node’s antenna is inside the enclosure. Furthermore, the casing can shield the sensor node from the sun and weather conditions, as well as keeping the internal temperature higher than the external one.

Since the control and emergency systems require that data is transported timely and reliably, it is necessary that the communication protocols are capable of achieving the required communication performance even if the quality of the wireless channel is fluctuating. To enable an efficient design of such protocols, we study the range and the variance of these fluctuations with respect to the changes in ambient temperature and the use of ATEX casing.
III. IMPACT OF TEMPERATURE ON COMMUNICATION

The outdoor deployment in the refinery is affected by frequent temperature changes and different weather conditions. Hardware components for outdoor deployments are usually designed for an operating temperature range from $-40 \degree C$ to $+85 \degree C$. Temperature changes, however, cause a shift of the crystal frequency, increased thermal noise of the transceiver, and saturated amplifiers [4], resulting in degraded radio performance [5], [6].

A. Sentilla Tmote Sky Platform

To quantify the impact of temperature on a communication link, several experiments involving a couple of Tmote Sky nodes were carried out. The Sentilla Tmote Sky [7] uses the Chipcon 2420 radio chip [8] which operates at 2.4 GHz. The nodes run the Contiki operating system [9] with a customized application for the experiment. One node is used as a transmitter and the other node is a receiver. 256 packets, each with a 12-byte payload, are transmitted every 4 seconds. Nodes are placed at 3 meters distance, and their transmission power is kept at -3 dBm throughout the experiment. We use different 802.15.4 channels to make sure that specific interference on a channel is not biasing the data. The receiver logs the averages of the Received Signal Strength Indicator (RSSI), the Link Quality Indicator (LQI), the local temperature, and the sender’s temperature which is contained in the received packets. The receiver also records the RSSI noise floor immediately after receiving each packet.

Different runs are carried out under different conditions: first both the sending node and the receiving node are exposed to an increase of temperature from between $-15$ and $-3 \degree C$ to $+53 \degree C$ in 90 minutes. The results of this experiment are shown in Figure 3. As we can see from the figure, the impact of temperature on the radio chip is considerable, and the higher the temperature is, the lower are the signal strength and the link quality. Figure 3 shows a signal strength drop of approximately 9 dBm. This is a substantial reduction, given that the typical range is between 0 and -100 dBm. Hence, high temperatures might lead to a loss of connectivity within the sensor network. Each point plotted is the result of an average operation over 256 packets. This enables us to monitor more precisely how the signal strength and link quality decrease, since the nominal RSSI and LQI are integer values.

Figure 4 shows that the RSSI noise floor decreases as well with temperature. This is an important observation because this value is often used by the medium access control (MAC) layer to determine if the channel is currently busy or not, and, as Figure 4 shows, also the noise floor is temperature dependent.

Under the same conditions, a second batch of experiments was carried out. Differently from the previous run, only the receiver node was exposed to a thermal variation from approximately $-10 \degree C$ to $+55 \degree C$ in 90 minutes. In this run we noticed a drop of approximately 4 to 5 dBm in the RSSI when the temperature reaches the highest values. This variation is approximately 50% less than the one caused when both nodes are exposed to a thermal change. The RSSI noise floor decreases following the same pattern as in Figure 4.

![Fig. 3. Temperature impact on the RSSI and LQI indicators of the CC2420 radio chip when both sender and receiver nodes are affected by the thermal variation. Data is measured using the Sentilla Tmote Sky platform.](image1.png)

![Fig. 4. In addition to the RSSI and LQI indicators, temperature has also an impact on the RSSI Noise floor readings of the CC2420 radio chip. Data is measured experimentally using the Sentilla Tmote Sky platform when both sender and receiver nodes are affected by the thermal variation.](image2.png)

We also carried out a third batch of runs in which only the sending node was exposed to a thermal change. Also under these conditions, we notice a drop of approximately 4 to 5 dBm in the RSSI when the temperature reaches the highest values.

Unlike the other two sets of experiments, however, no significant difference was noticed on the RSSI noise floor. We can thus infer that the drop shown in Figure 3 is the sum of two equal contributions: one due to the heated receiver, and one due to the heated sender.

B. Scatterweb MSB-430 Platform

In a second set of experiments we used the Scatterweb Modular Sensor Board [10] (MSB430) platform. This platform uses a CC1020 [11] radio chip running at 868 MHz. The experimental setup was similar to the setup used for the previously described experiment. However, only the RSSI and RSSI noise floor were recorded since the LQI is not available in the CC1020 radio.

As in the previous experiment, the impact on communication is highest when both sensor nodes are exposed to thermal change. Figure 5 shows the RSSI drop when temperature increases from $-10 \degree C$ to $+50 \degree C$. The results show a similar dependence between temperature and RSSI as in the previous experiment: Figure 5 shows a signal strength drop of approximately 6 dBm over the investigated temperature range. Like with the Tmote Sky platform, the noise floor of the MSB430 platform also is affected by temperature, as shown in Figure 6.
that also the transmission power is influenced by temperature.

obtain when transmitting at lower temperatures. This implies
power to obtain the same signal strength as is possible to
running at high temperatures needs a higher transmission
warmed. At the same time, this means that a sensor node
ments the RSSI at the receiver decreases when the sender is
increase with the increasing temperature if the transmissi-
on the radio chip negatively, the signal strength of transmis-
from the antenna) of the receiver [4], [5].

Fig. 5. Temperature impact on the RSSI of the CC1020 radio chip when
both sender and receiver nodes are affected by the thermal variation. The data
is measured using the Scatterweb MSB430 platform with an SMA antenna.

C. Discussion of the Obtained Results

From our experimental results it can be concluded that the
observed temperature dependency exists on different platforms
and for different radio frequencies. The observations are not
antenna specific as the temperature impact is visible on both
the Tmote Sky which has a built-in PCB antenna, and on the
MSB430 which uses an external antenna connected via SMA.
The effects are caused by the radio chip. More precisely,
the components affected by temperature are the power amplifi-
er of the transmitter and the LNA (that amplifies the RF signal
from the antenna) of the receiver [4], [5].

If a temperature increase affects the power amplifier of the
radio chip negatively, the signal strength of transmissions will
decrease with the increasing temperature if the transmission
power is constant. This partially explains why in our experi-
ments the RSSI at the receiver decreases when the sender is
warmed. At the same time, this means that a sensor node
running at high temperatures needs a higher transmission
power to obtain the same signal strength as is possible to
obtain when transmitting at lower temperatures. This implies
that also the transmission power is influenced by temperature.

In addition to this, the RSSI is further reduced when the
receiver is exposed to high temperature, which is due to the
lower LNA amplification. This impacts only the values of
RSSI and RSSI noise that are returned by the chip because the
environmental noise obviously does not decrease with

Fig. 6. In addition to the RSSI, temperature has also an impact on the RSSI
Noise floor readings of the CC1020 radio chip. The data is measured using
the Scatterweb MSB430 platform with an SMA antenna. Both sender and
receiver nodes are affected by the thermal variation.

IV. THE ATEX CERTIFICATION REQUIREMENT

In order to achieve ATEX compliance, sensor nodes can be
enclosed in ATEX compliant casings. This procedure avoids
costly certification procedures, especially for small modifica-
tions of the sensor node hardware.

A. ATEX Enclosures

When sensor nodes are enclosed in ATEX-compliant cases,
the radio propagation might be affected by the casing. We
conducted several experiments to evaluate if there is a
decrease of performance when sensors are enclosed into
ATEX cases. However, the results did not show a negative
systematic trend of the RSSI when the nodes are inside the
case. This applies at different distances and locations, both
indoor and outdoor. The node’s orientation, the deployment
location, the presence of obstacles in the surroundings, and
the environmental interference are the variables that affect the
radio signal reception rather than the presence of the casing.

B. ATEX Enclosures and Temperature

The ATEX case does not have an impact on radio propaga-
hence does not affect communication directly. How-
ever, the casing has an effect on the temperature of the sensor
node and, thus, has an indirect impact on communication.

A high temperature inside the ATEX case can be detrimental
to low-power communication, and the temperature effect is
largest when the internal temperature of both the cases of
sender and receiver is high. After carrying out the same set of
experiments as in Section III-A, but enclosing both the sensor
nodes in ATEX casings, we detected a rise in the RSSI of
approximately 9 dBm, as shown in Figure 7.

The experimental results show again that temperature
changes have a significant impact on communication. In order
to ensure stable communication links, it might therefore be
useful to avoid nodes exposed to direct sunlight. In the inves-
tigated refinery scenario this is possible since the deployment
is highly controlled, and sensors are not deployed randomly.

The airtight ATEX casing creates a warming effect that
increases the inner temperature. In our application, the tem-

Fig. 7. Sensor nodes enclosed in an ATEX-compliant casing: a high
temperature inside the case can be detrimental to low-power communication.
Confirming the previous results, the RSSI decreases when the temperature
increases. Temperature varies in the ATEX case of both sender and receiver.
the performance of the network or disrupt the connectivity between sensors. A high temperature—partly caused by the warming effect—can reduce the received signal strength.

For this reason we inspect the behavior of the temperature inside the ATEX casing with different weather conditions at different hours of the day. We use Contiki [9] and Sentilla Tmote Sky nodes equipped with Sensirion SHT11 temperature sensors [12] to perform such outdoor experiments. We compare the behavior of nodes enclosed in ATEX-compliant cases with nodes that are not enclosed. Figure 8 shows how, during the night, the casing creates a warming effect on the sensor nodes, and the temperature inside the case is higher than outside. The bottom figure shows that when the sun shines directly on the sensor motes, the case shields the nodes, and slows down the inner increase of temperature.

\[ \text{Outside ATEX casing} \quad \text{Inside ATEX casing} \]

Fig. 8. Temperature registered on Tmote Sky nodes placed inside and outside ATEX-compliant enclosures at different hours of the day. The top figure shows how, during the night, the casing creates a warming effect on the sensor nodes, and the temperature inside the case is higher than outside. The bottom figure shows that when the sun shines directly on the sensor motes, the case shields the nodes, and slows down the inner increase of temperature.

V. THE IMPACT OF TEMPERATURE ON TX POWER

Sections III and IV describe the influence of temperature and ATEX enclosures on transmission links in industrial outdoor deployments. The experimental results show that an increase in temperature leads to a reduction of the signal strength at the receiving side, due to the impact of temperature on the radio driver, and more precisely on the power amplifier of the transmitter [4], [5].

The impact of temperature on the power amplifier directly affects the strength of the outgoing radio signal: at higher temperatures the signal gets weaker. Therefore it can be expected that with an increase in temperature, a higher transmission power is required to maintain the same signal strength and thus to ensure successful data transmission.

We carried out several long-term outdoor experiments to investigate this effect. The aim was to determine the minimum transmission power level necessary to ensure successful data transmission between two Tmote Sky nodes. Given a pool of \( N \) packets, we define the minimum power to reliably communicate as the minimum power necessary to achieve 100% delivery, i.e. we expect exactly \( N \) received packets. Furthermore, we define the minimum power to barely communicate as the minimum power necessary to receive at least one packet, without caring about the actual delivery rate.

A. Experimental setup

We deployed the nodes in pairs consisting of a sending and a receiving node running the Contiki operating system [9]. The sender transmits a train of 15 packets with 2-byte payloads, starting with the highest transmission power available. Each packet contains a sequence number and the information about the transmission power used by the sender. The receiving node uses the same transmission power as advertised in the message to reply to the sender. The receiver sends an acknowledgment for every received packet, identified by its sequence number. If the sender receives at least one acknowledgment for the 15 packets sent, it will decrease the transmission power by one unit. We did not use a MAC protocol to organize channel access as we wanted to analyze only channel characteristics. We use static Tmote Sky nodes to run this experiment during different days and nights.

B. Transmission power levels in the CC2420 radio

The transmission power in the CC2420 radio driver can be set into 32 different values, ranging from roughly -55 dBm to 0 dBm through the PA\_POWER register. Unfortunately, the CC2420 datasheet [4] documents only 8 discrete levels ranging from -25 dBm to 0 dBm, and the radio manufacturer confirms that the relationship between the register setting and the output power is not linear [13]. However, in order to compute the unknown values, estimations have been used, such as the cubic spline interpolation [14]. We measured the current consumption for all PA\_POWER values experimentally using an oscilloscope. This is an important contribution of this paper, as information about the transmission power of the CC2420 does not exist [13], [14]. We measure the current consumption...
The importance of measuring the value for each power level. These
we confirm that the slope is not linear, which shows the
characteristic of the current consumption of the
100Ω
oscilloscope [15] over a resistance of
the values provided by the CC2420 manual and the experimental results.

Fig. 9. Current consumption in the CC2420 radio chip. The left figure shows
the current measured with the oscilloscope while increasing the PA\_POWER
level from 0 to 31. The first spike occurs because the radio is switched on and
needs to be initialized (INIT). The right figure shows a comparison between
the values provided by the CC2420 manual and the experimental results.

Fig. 10. Minimum transmission power required to communicate by two
sensor nodes. During daytime the sun shines directly on the motes, and
increases significantly the temperature on the board. With respect to nighttime
operations, the sensor nodes require roughly 16% more energy for a successful
transmission during the hottest time of the day. In this example, sensor nodes
were deployed at a distance of around 7 meters and were exposed to sunlight
from 8:00 to 11:00.

of the different PA\_POWER levels using a Velleman PCSU
1000 oscilloscope [15] over a resistance of 100Ω. Figure 9
shows the characteristic of the current consumption of the
Chipcon CC2420 radio that we measured experimentally.
We confirm that the slope is not linear, which shows the
importance of measuring the value for each power level. These
values are used to calculate the current consumption for the
PA\_POWER values not specified in the CC2420 manual.

C. Experimental results

Our experimental results show that the minimum transmission
power to communicate is considerably affected by tem-
perature variations. This applies for temperature fluctuations
between day and night and for changing weather conditions as
well. All the results we obtained in our runs show a significant
increase in the minimum transmission power, indicating that
reducing the transmission power during the coldest time of the
day or the year may help in saving energy.

Figure 10 shows a daily deployment in Germany during the
summer, and we can see that when the sun shines on the sensor
nodes, the temperature reaches up to 70 °C, thus 55 °C higher
than during the night. Nodes are not exposed to wind, and
they are placed approximately 7 meters away from each other.
The high thermal variation causes an increase of the minimum
transmission power to barely communicate from PA\_POWER
11 to 17. At the same way, the minimum transmission power
to reliably communicate increases from PA\_POWER 13 to 22.
According to our experimental results shown in Figure 9, the
current consumption increases by 11.4% in the first case, and
by 16.3% if we want to achieve a 100% delivery rate.

During this experiment, both sender and receiver nodes are
affected by high temperature changes. This implies that in
addition to the sender transmissions, also the acknowledg-
ments sent from the receiver need a higher transmission power to
reach their destination.

Figure 11 shows a deployment in Sweden during the end
of August. The results are relative to a sunny weekend, where
only the sending node is exposed to the sunlight. We can see
that when the sun shines directly on the mote, the temperature
increases up to 48 °C, thus 25 °C higher than during the night.
Nodes are not exposed to wind, and they are approximately
13 meters far away from each other. The nodes are placed
in such a position that they cannot achieve 100% delivery
even with the highest transmission power available. However,
we notice how the minimum transmission power to barely
communicate increases from PA\_POWER 20 to 28 when the
temperature increases. According to our experimental results
shown in Figure 9, the current consumption needed to barely
communicate increases with 10.1%. This result confirms that
even when the temperature variation is not as high as it was
in the deployment in Germany, the impact of temperature
is still considerable.

Another experiment was carried out in Sweden during
the spring using different distances between the two Sky
nodes (the distance was gradually increased from 50 cm to
20 m). The minimum transmission power was then compared
when temperature in both nodes was 18 °C and 38 °C
respectively. Figure 12 shows the results of the experiments,
where PA\_POWER represents the transmission power level
used in the CC2420 radio. The plot shows the minimum
transmission power to barely communicate, and confirms that
the temperature impact applies at all distances.

We further checked whether the nightly operations were requiring less energy because of the reduction in temperature or because of the minor environmental noise. During night there is not only a decrease in temperature but also a reduction of ambient noise because generally fewer electric devices are operating. We carried out many different experiments, and the ones shown in Figure 10 and 11 were explicitly chosen since they do not suffer from external interference. In the first plot, the sun is shining on the two motes only from 8:00 to 11:00, while the motes were in the shadow during the midday and the afternoon. We can clearly see that both temperature and transmission power decrease after 11:00, showing that the correlation is with the temperature rather than with the environmental noise. The second experiment is carried out in an office during weekends, so to avoid external interference.

In summary, our experimental results show that reducing the transmission power during nighttime and the coldest time of the year is a good practice that can save up to 16% of the energy consumption. Creating a control loop algorithm that adapts the transmission power to the temperature sensed by the sensor nodes may thus help to increase the overall network lifetime. Beside the temperature impact, it is also good to keep the transmission power as low as possible, because increasing the transmission power may result in more contention, although the link quality improves [16].

VI. IMPACT ON APPLICATION SCENARIO

The influence of temperature variations on communication link quality must be taken into account when deploying a wireless sensor network in the application context outlined in Section II. In particular, the following aspects should be considered when designing and deploying a sensor network for the oil refinery context:

Deployment Time: The time chosen to deploy and test the equipment in the refinery is crucial. New devices within the refinery are typically deployed and tested during the evening or night when the refinery is at its quietest. In the south of Portugal, temperatures can vary in the summer between 35 °C during the day and 20 °C during night times. In addition, some of the nodes may be exposed to direct sunlight which will increase the temperature even further (see Figure 10). Thus, temperature variations between 18 °C and 38 °C as used to derive results shown in Figure 12 have to be expected. The graph shows that two devices can communicate over a greater distance when the environmental temperature is lower than at times of higher temperature. For example, a communication link configured with a transmission power level 3 to span a 5 meters distance at night will only be able to cover a distance of 2 meters during the day, which might result in a disconnected network. Hence, devices deployed and tested during the usual refinery maintenance period (which coincides with the coldest time) may not be able to communicate during daytime, when temperatures are higher. Therefore it is important that the communications are tested during the hottest times of the year.

Maintenance: Wireless sensor nodes within the refinery will be battery powered and therefore only have a finite lifetime. Continued operations can only be ensured when batteries are replaced before depletion. The cost of replacing batteries of 35,000 nodes within the refinery is very high and cannot be neglected. Maintenance personnel must be employed to ensure that batteries are replaced at the right time, which accounts for the largest part of the maintenance cost, while actual material cost for batteries is insignificant in comparison. Hence, it is important to achieve a long node lifetime to reduce the maintenance frequency. It is not advisable to use the maximum transmission power that a node provides. To conserve energy, the power should be set to the minimum required to bridge the required distance. Given the results shown in Figures 10, 11, and 12 the temperature dependency of the transmission power should be taken into account as well. Saving energy during nighttime and during the coldest seasons prolongs the battery duration, and therefore it is worth considering to adapt the transmission power to the ambient temperature.

Protocol Design: As pointed out in the previous paragraph it is necessary to take temperature into account also when deciding which transmission power should be used. Ideally, a node should adapt automatically to the proper transmission power setting. Generally, it is difficult to construct a stable adaptive algorithm if the temperature is fluctuating heavily over a short time span. However, as shown in Figure 8, the ATEX casing shields the sensor node from erratic temperature changes. Hence, we believe it is possible to devise a stable and efficient algorithm for transmission power adaptation, such as the one shown by Hackmann et al. [16].

VII. RELATED WORK

Several researchers have shown that outdoor sensor networks are affected by weather conditions and temperature. Thelen et al. [17] described how radio waves propagate better under weather conditions with high humidity in their potato field deployment. The results of Anastasi et al. [18], Sun et al. [19], and Capsuto et al. [20] suggest that weather effects, specifically fog and rain, may have a severe impact on the transmission range of sensor nodes, in particular with respect to the packet reception rate. Bonno et al. [6] quantified the impact on rain and fog with respect to the signal strength and the link quality under different platforms, showing that
rainfall of less than 2-3 mm/hour has a negligible effect on the signal strength. When the rainfall is heavier, however, the connectivity might be disrupted.

Bannister et al. have shown that high temperatures negatively affect communication between sensor nodes [5]. In their deployment in the Sonoran Desert of the southwestern United States, the reduction of the signal strength was largest during the hottest time of the day. We quantify the impact of temperature also at lower temperatures, using different platforms and radio frequencies. We show that also the LQI, in addition to the RSSI, is affected. This is very important, since RSSI and LQI are used often to estimate the future packet reception rate of communication links [21], [22].

Unlike previous work, we show the influence that temperature has on the minimum transmission power necessary for communication between sensor nodes. We show that sensor networks operating at low temperatures can decrease their transmission power and save up to 16% energy, and thus increase their lifetime. To the best of our knowledge, this is a novel contribution. There are different protocols implemented to adapt the transmission power such as ATPC [23], but they adapt the transmission power based on neighbor status.

In order to obtain a high precision in our results, we measured the current consumption of all the 32 output power levels in the CC2420 radio chip. Our experimental results fill up the knowledge gap in the information provided by the manual [8] that is limiting researchers’ work, as highlighted by Hauer et al. [13]. In this way, we evaluate the precise amount of energy saved, without resorting to empirical or statistical approaches as others have done [14] or using only the transmission channels for which the power consumption is provided by the manual as done by Hackman et al. [16]. We show how obtained transmission power is non-linear in relation to the configured power level (PA_POWER), and that a regression may not be the appropriate choice.

Most sensors for industrial control and automation applications must comply with the ATEX directive 94/9/EC [1] for equipment and protective systems intended for use in potentially explosive atmospheres. To the best of our knowledge, there are no studies that assess if compliance with this standard has an impact on wireless sensor networks performance. Our measurements aim to close this knowledge gap.

VIII. CONCLUSIONS

In this article we investigated the temperature influence on low-power communications. For our case study, we used the deployment of an outdoor wireless sensor network in an oil refinery in which ATEX compliance is a necessity. Our experimental results show that temperature has a major effect on signal strength and link quality, and that operations at lower temperatures might require up to 16% less power to maintain a reliable communication. We have further explained how this affects the deployment and the design of the network in the refinery. We believe that the findings presented in this article can help to improve the design of wireless sensor network deployments for industrial process and control applications. Furthermore, the presented results can be used to construct energy-efficient protocols that adapt the transmission power to the measured ambient temperature in order to save energy and increase the lifetime of the system.
